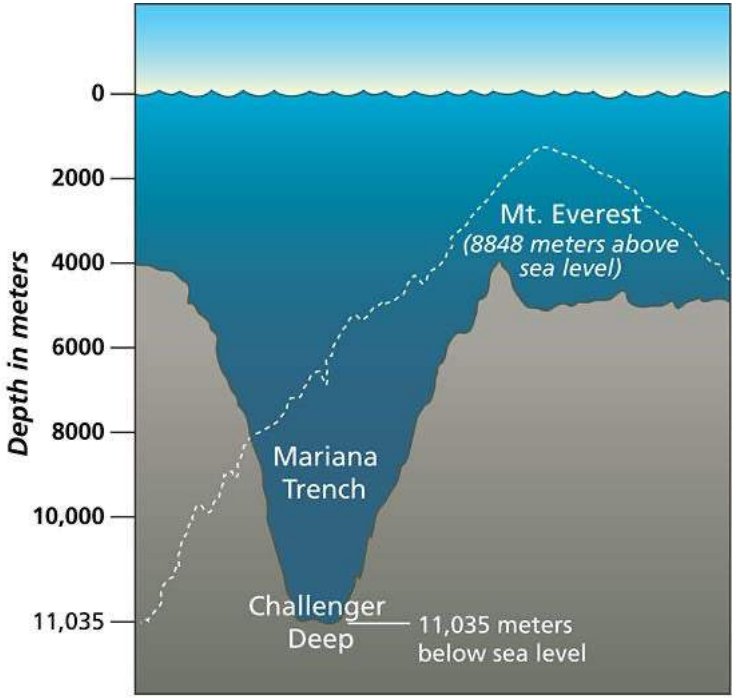
What is High Energy Density Physics (HEDP)?

- Pressure above 1 Mbar = 1 million atm
- ~ Boeing 747 on your fingertip

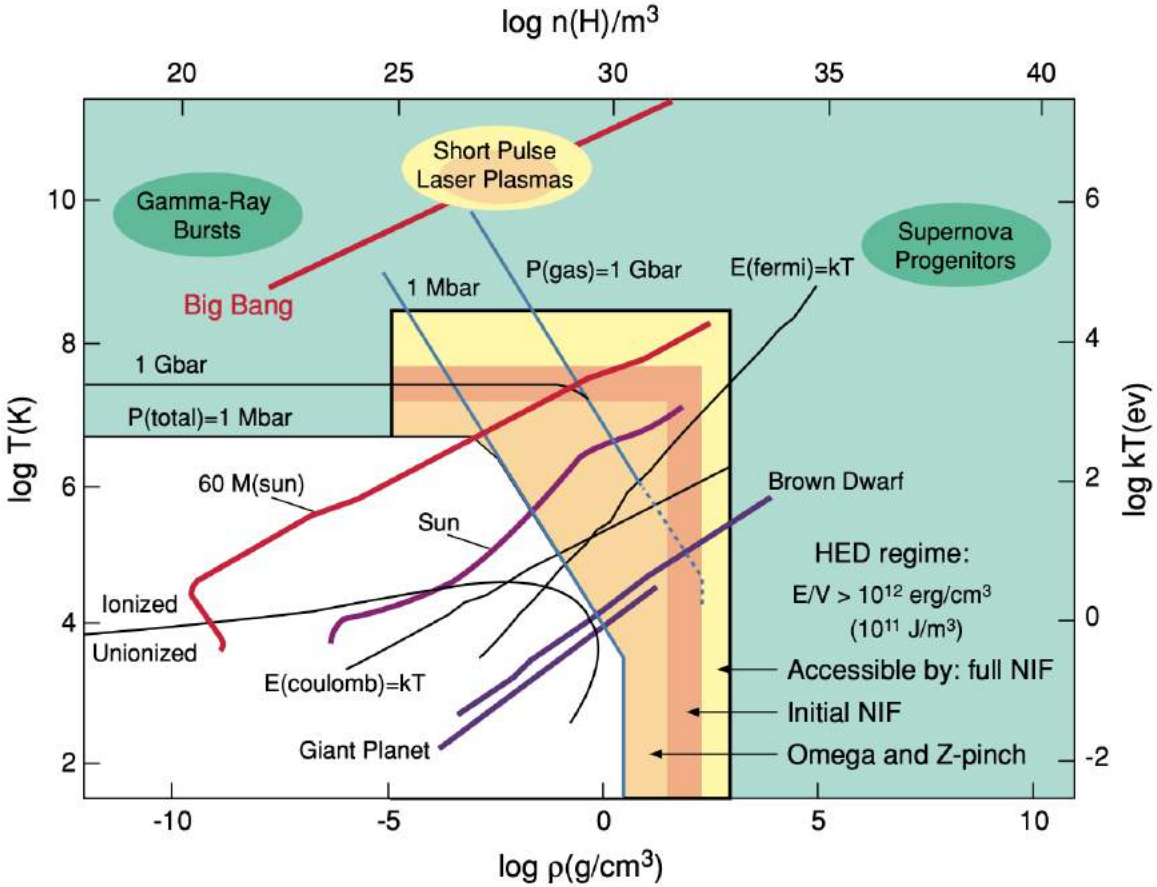
$$P = \frac{F}{A}$$

1000 atm →

- In the ocean, reach
  - 1 atm at 10 m
  - 1 Mbar at 10^6 m (10 million meters)



What is HEDP?



1 eV ~ 10,000 K

1 MeV ~ 10^{10} K

- At high density, get pressure ionization
- The lines for P = 1 Mbar, etc indicate the T_e at which an equilibrium radiation field produces these pressures
- Strongly coupled: to the right of the line $E(Coulomb) = kT$, energy of Coulomb interactions exceeds the thermal energy

[Frontiers in High Energy Density Physics: The X-Games of Contemporary Science, National Research Council (2003)]

What is HEDP?

- Fermi degenerate: to the right of the line $E(Fermi) = kT$, the Fermi energy exceeds the thermal energy
- # of electrons in a Debye sphere:

$$\Lambda = 4\pi n_e \lambda_D^3$$

$$\lambda_D^2 = \frac{\varepsilon_0 k_B T_e}{n_e e^2} \quad \rightarrow \quad \Lambda = 4\pi\varepsilon_0 \frac{(k_B T_e)^{3/2}}{n_e^{1/2}}$$

- If Λ is small → non-ideal plasma
- For HED matter, it's typically a plasma, but plasma theory may not be sufficient

High Energy Density Physics

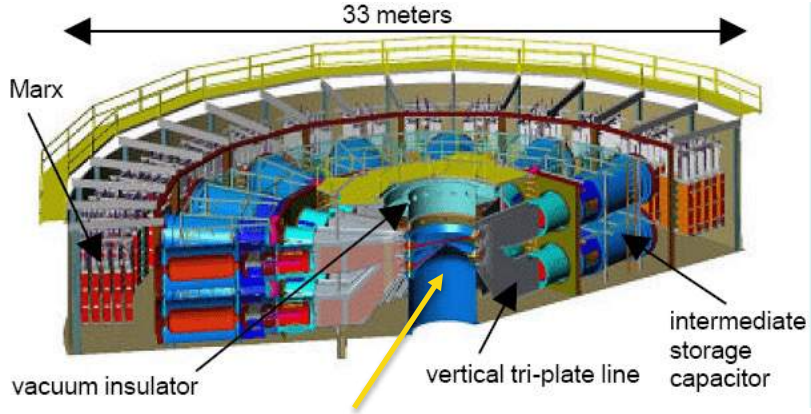
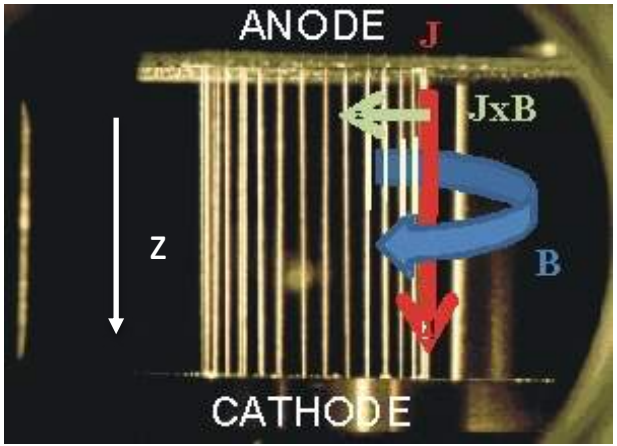
Creating HEDP conditions: Z-pinch

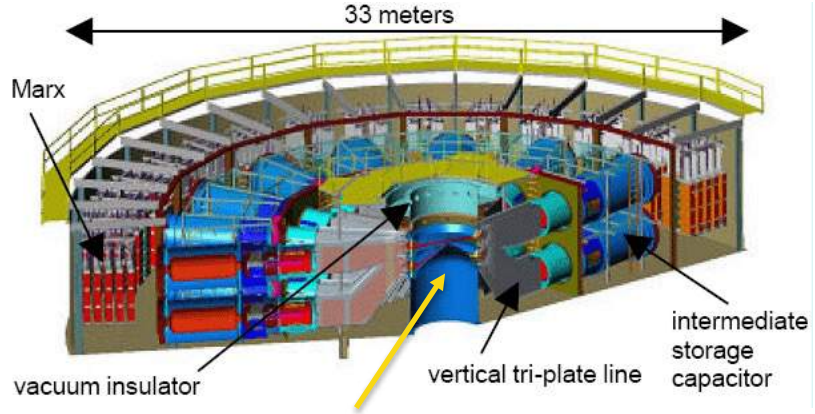


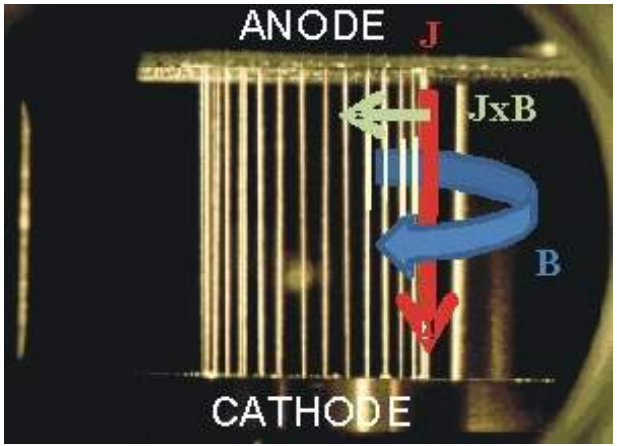


Wire array

Wires are heated by the current, and ablate plasma

Creating HEDP conditions: Z-pinch



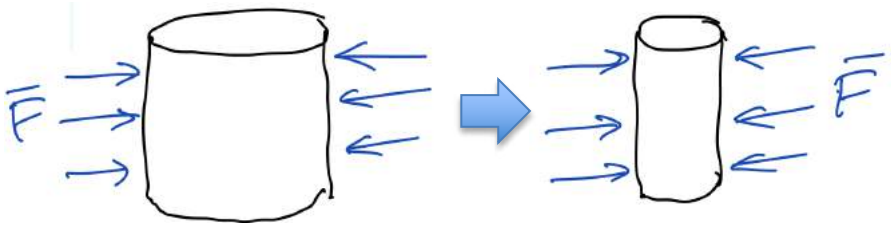


Wire array

Force on the plasma due to magnetic pressure (Lorentz force)

$$\bar{F} = \frac{\bar{J} \times \bar{B}}{v} = -P_{mag} 2\pi R h$$

Where R = radius and h = height



- Assemble dense, hot plasma on axis
- Source of bright x-rays
- Instabilities: sausage, kink, magneto RT

Creating HEDP conditions: Laser pulses

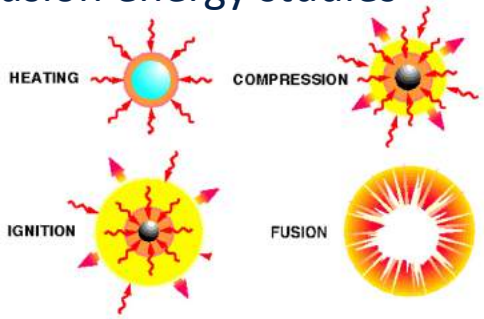
NIF at LLNL

Aka “The Warp Core” on StarTrek

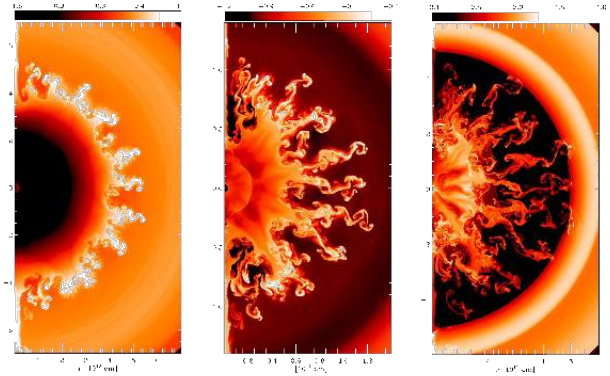
What can these facilities study?

…planetary interiors, equation of state, atomic processes, radiation transport, photoionization, stellar opacity, magnetic reconnection, particle acceleration, collisionless plasmas, turbulent dynamos, nuclear astrophysics, pair plasmas...

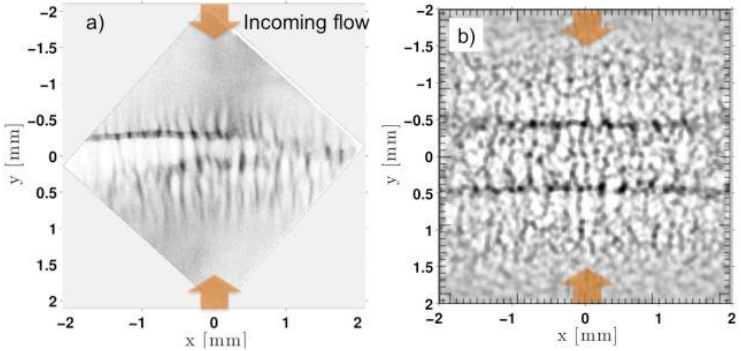
Fusion energy studies



Basic plasma instabilities



Fundamental & nuclear physics



Equation of state

Target plasma density

If the laser frequency, ω_L, equals the electron plasma frequency

$$\omega_L = \omega_{pe} = \sqrt{\frac{n_e e^2}{\varepsilon_0 m_e}}$$

then the critical density is found:

$$n_{cr} = \frac{m_e \varepsilon_0 \omega_L^2}{e^2}$$

Target plasma densities

$$n_c = \frac{m_e \epsilon_0 \omega_L^2}{e^2}$$

$\lambda = 1\mu m$

$n_c = 10^{21}$ cm^{-3}

n_e

Underdense

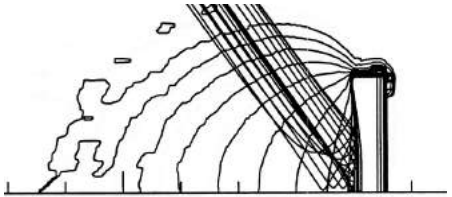
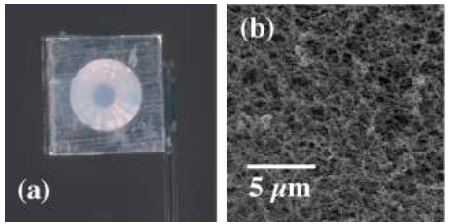
Plasma plume

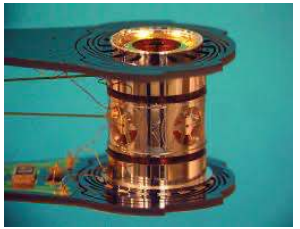


Foam

$0.9 – 30 \times 10^{21}$ cm^{-3}



Solid foil ~ 10^{24} cm^{-3}



Blackbody radiation

Hot material radiates energy as photons

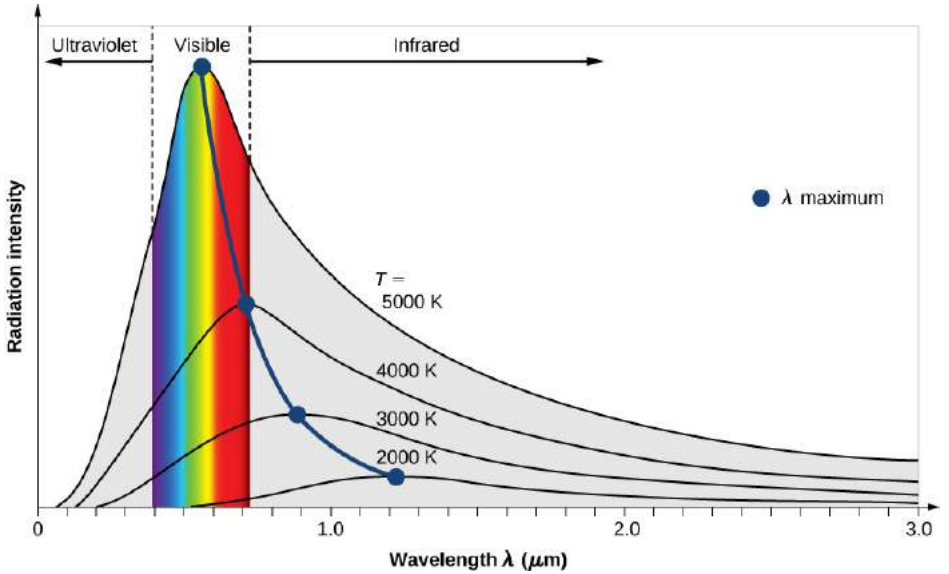
Blackbody radiation spectrum is given by Planck's law:

spectral radiance (power / unit solid angle / unit area normal to propagation) density of frequency, ν, radiation per unit frequency at thermal equilibrium at temperature T,

$$B_\nu(T) = \frac{2h\nu^3}{c^2}\frac{1}{e^{h\nu/kT} - 1}$$

Planck constant, $h = 6.6\times10^{-34}$ Js $= 4.1 \times10^{-15}$ eV.s

Blackbody radiation is isotropic

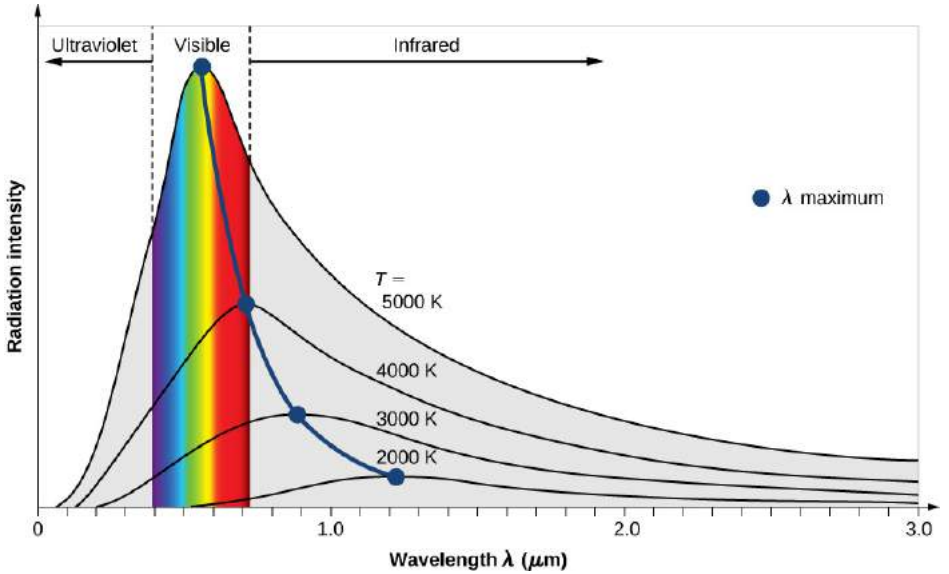


Higher T:

- Peak shifts to lower λ (higher photon energy)
- Radiation intensity increases

Blackbody radiation

- We can use laser pulses to heat materials to high temperatures
- The material will then radiate a blackbody spectrum…



Higher T:

- Peak shifts to lower λ (higher photon energy)
- Radiation intensity increases

Radiation hydrodynamics

- Plasma gains or loses energy and momentum through photon emission, absorption, and/or scattering.
- This modifies the fluid energy equation and can alter hydrodynamics

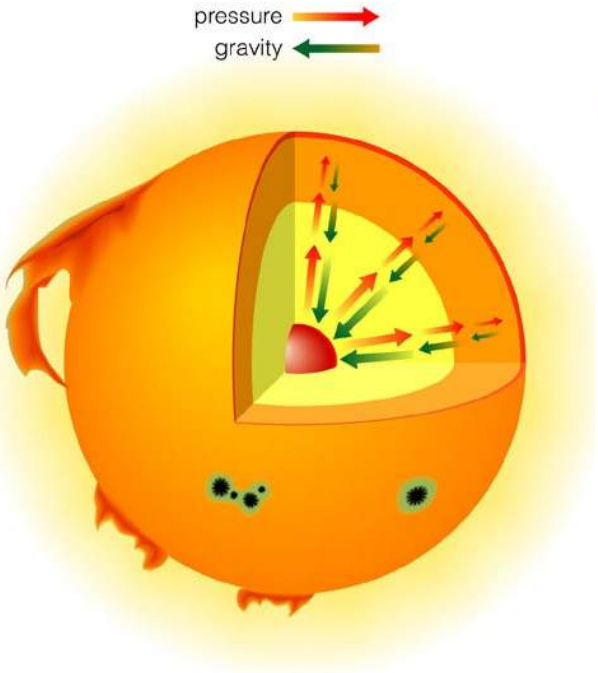
- Radiation flux is given by σT^4 (Stefan-Boltzmann Law)
- The radiation hydrodynamics regime is affected by the material, the density and temperature.
- If radiation flux > material energy flux, then it's a radiation dominated regime

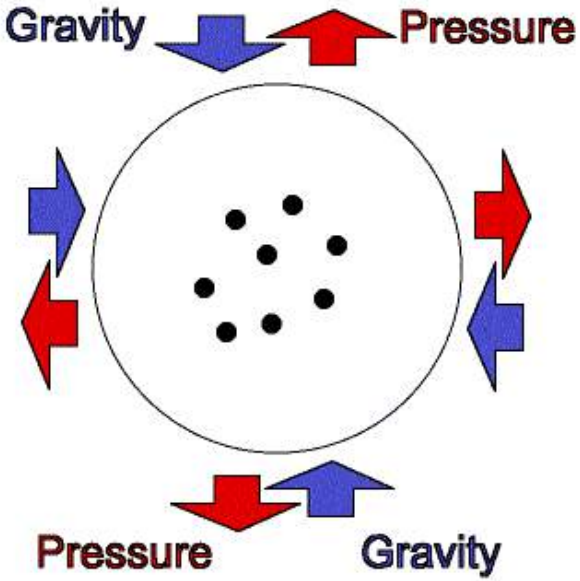
Radiation effects

Fluid effects

We can drive experiments with blackbody radiation

Creating a star on Earth



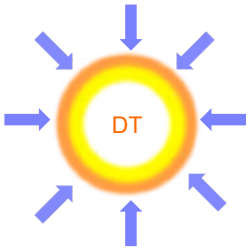


Thermonuclear fusion heats the inside of the star, creating pressure that stops the collapse and producing a long period of great stability that defines the main sequence

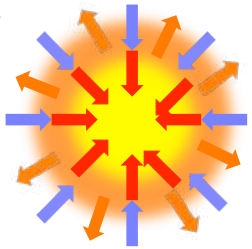
Inertial Confinement Fusion (ICF)

Radiation Blow-off Inward transported thermal energy

1. Laser beams or laser-produced x-rays rapidly heat the surface of the fusion target, forming a surrounding plasma envelope

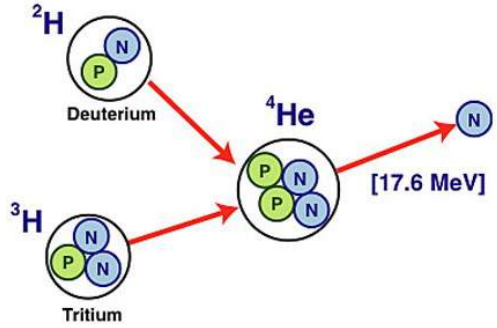


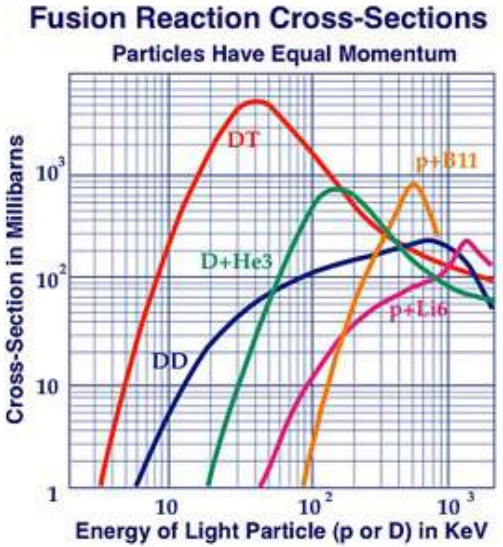
2. Fuel is compressed by the rocket-like blow off of the hot surface material



3. During the final part of the capsule implosion, the fuel core reaches 20 times the density of lead and ignites at 100,000,000°C

4. Thermonuclear burn spreads rapidly through the compressed fuel, yielding many times the input energy





Inertial Confinement Fusion

- Hot spot conditions:
- How dense? ~ 100x solid lead (600 – 800 g/cc)
- How hot? > 100 million K
- How long? ~ 10 ns

Abstract

Magnetic fields are ubiquitous in the Universe. The energy density of these fields is typically comparable to the energy density of the fluid motions of the plasma in which they are embedded, making magnetic fields essential players in the dynamics of the luminous matter. The standard theoretical model for the origin of these strong magnetic fields is through the amplification of tiny seed fields via turbulent dynamo to the level consistent with current observations. However, experimental demonstration of the turbulent dynamo mechanism has remained elusive, since it requires plasma conditions that are extremely hard to re-create in terrestrial laboratories. Here we demonstrate, using laser-produced colliding plasma flows, that turbulence is indeed capable of rapidly amplifying seed fields to near equipartition with the turbulent fluid motions. These results support the notion that turbulent dynamo is a viable mechanism responsible for the observed present-day magnetization.

Turbulent dynamo

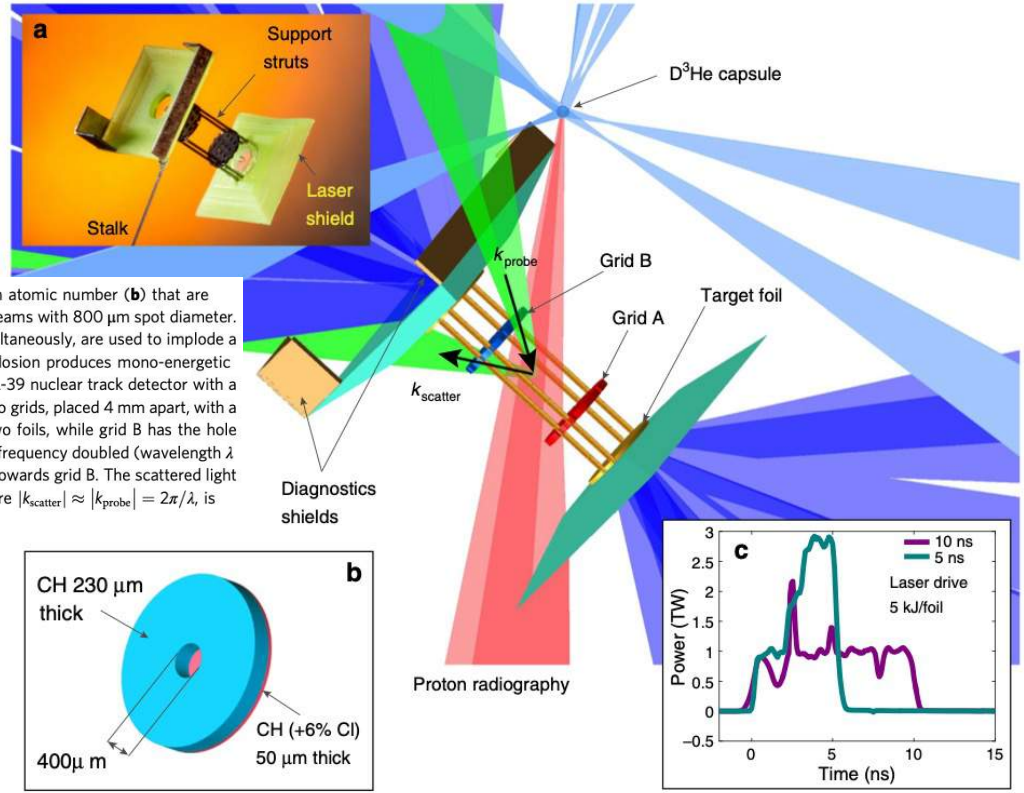

Fig. 1 Experimental configuration. The main target (see photo in **a**) consists of two CH foils doped with 6% chlorine in atomic number (**b**) that are separated by 8 mm. Each foil is illuminated by ten 500 J, 1 ns pulse length, frequency tripled (351 nm wavelength) laser beams with 800 μm spot diameter. The beams are stacked in time to achieve the two pulse profiles shown in **c**. An additional set of 17 beams, all fired simultaneously, are used to implode a 420 μm diameter capsule consisting of a 2-μm-thick SiO_2 shell filled with D_2 gas at 6 atm and ^3He at 12 atm. The implosion produces mono-energetic protons at 3.3 and 15 MeV with ~40 μm diameter source size, which traverse the plasma and are then collected by a CR-39 nuclear track detector with a total magnification factor of 28. The plasma expansion towards the center of the target is perturbed by the presence of two grids, placed 4 mm apart, with a 300 μm hole width and 300 μm hole spacing. Grid A has the central hole aligned on the center axis connecting the two foils, while grid B has the hole pattern shifted so that the central axis crosses the middle point between two holes. Thomson scattering uses a 30 J, 1 ns, frequency doubled (wavelength $\lambda = 526.5$ nm) laser beam to probe the plasma on the axis of the flow, 400 μm from the center and in a 50 μm focal spot, towards grid B. The scattered light is collected with 63° scattering angle and the geometry is such that the scattering wavenumber $k = k_{scatter} - k_{probe}$, where $|k_{scatter}| \approx |k_{probe}| = 2\pi/\lambda$, is parallel to the axis of the flow

https://www.nature.com/articles/s41467-018-02953-2

Turbulent dynamo

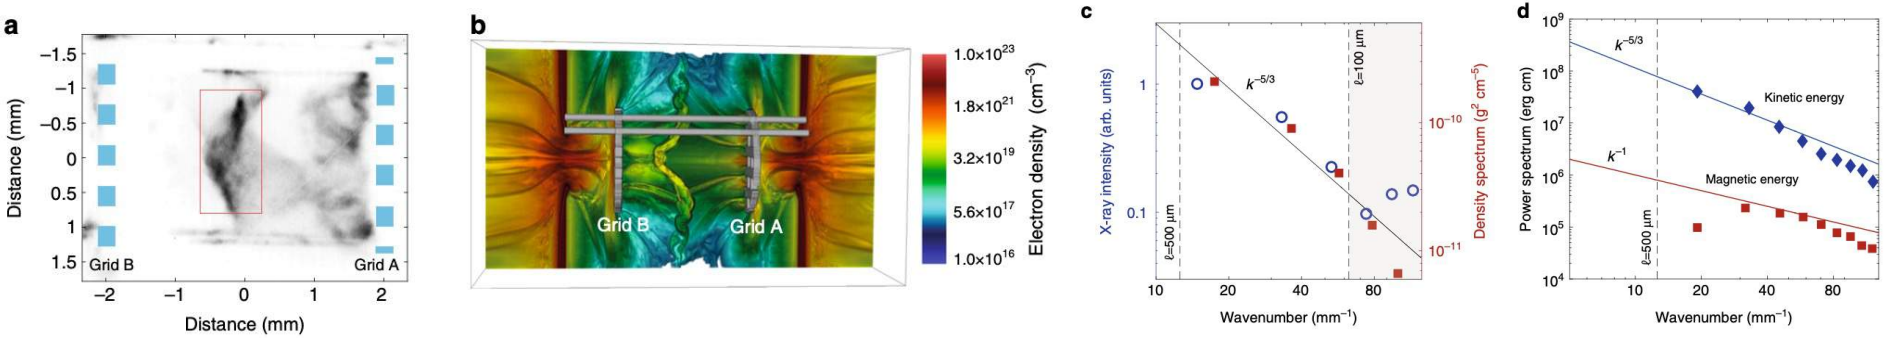

Fig. 2 Characterization of the plasma turbulence. **a** X-ray pinhole image of the colliding flows at $t = 35$ ns after the laser drive, using the 5 ns pulse profile. The image was recorded onto a framing camera with ~1 ns gate width and filtered with 0.5 μm C_2H_4 and 0.15 μm Al. The pinhole diameter is 50 μm. **b** Rendering of the electron density from three-dimensional FLASH simulations at $t = 35$ ns. **c** The open blue circles give the power spectrum of the X-ray emission from the collision region, defined by the rectangular region shown in panel **a**. The power spectrum has been filtered to remove edge effects and image defects. Details of this procedure are given in Supplementary Methods. The shaded region at high wavenumbers is dominated by noise. The spectrum of the density fluctuations, as obtained from FLASH simulations in the turbulent region, is shown with red squares. **d** Blue diamonds: power spectrum of the kinetic energy from FLASH simulations. Red squares: power spectrum of magnetic energy from FLASH simulations. The simulated magnetic energy spectrum is considerably shallower than the Kolmogorov-like kinetic energy spectrum, as predicted by ref. [23] and other studies in the Pm < 1 regime (see text)

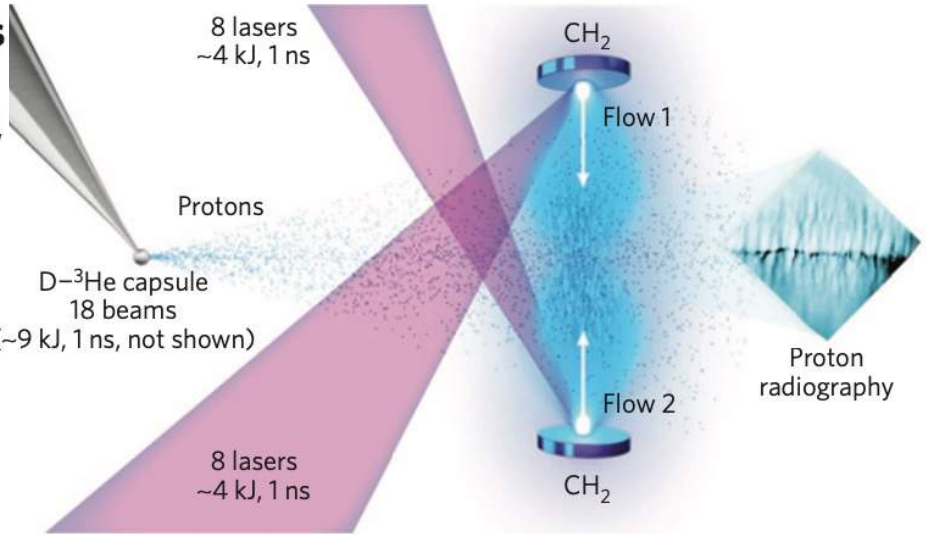

Figure 1 | Experimental configuration to generate opposing plasma flows probed by D–^{3}He protons. The experiment consists of a pair of (CH_2) plastic foils of diameter 2 mm and thickness 500 μm, oriented face-on and separated by 8 mm. Each was irradiated with eight overlapped laser beams, delivering ~4 kJ of 351 nm laser energy in a 1 ns square pulse. Distributed phase plates were used to produce super-Gaussian laser spots with focal spot diameters of 250 μm on the target surface. After a delay, the proton probe was created by laser-compressing a thin-walled SiO_2 capsule. The capsule was filled with a 1:1 mixture of deuterium (D) and ^{3}helium (^{3}He) at a total pressure of 18 atm. At peak compression (10^{23} cm^{-3}) protons are produced quasi-isotropically at energies of 3.0 and 14.7 MeV. The protons were detected using a CR39 nuclear track detector positioned on the midplane of the CH_2 target foils, such that the protons traverse the central interaction region as shown.

Plasma instabilities: Weibel

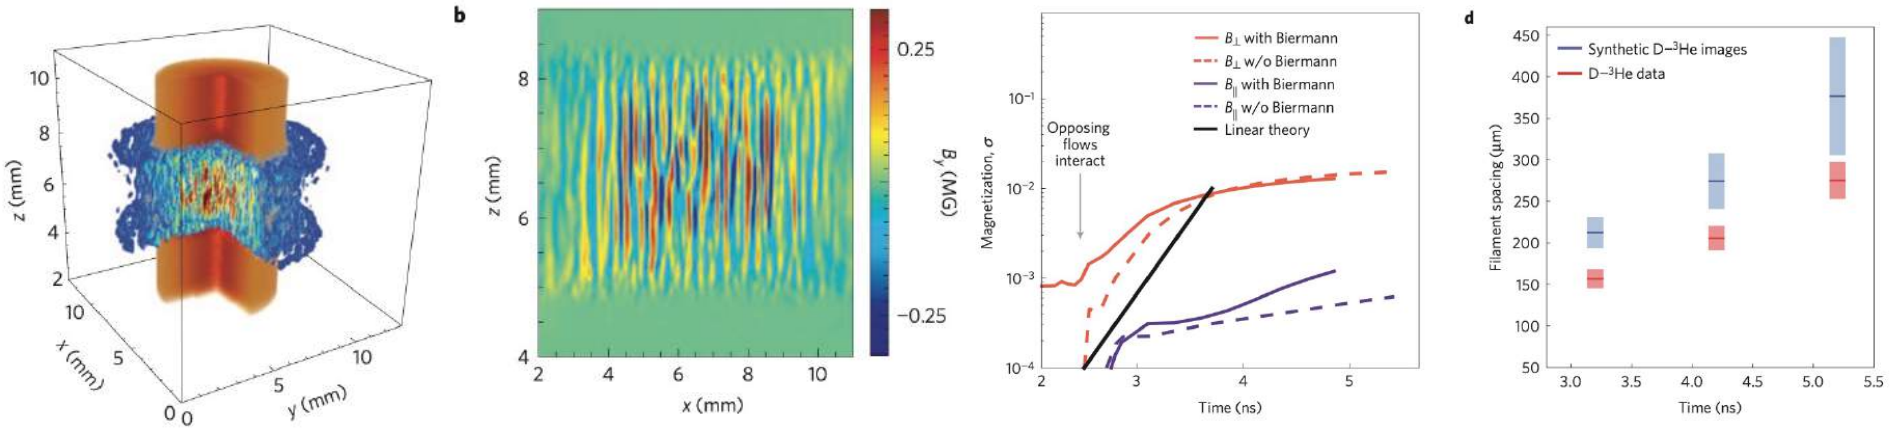

Figure 3 | Temporal evolution of magnetic field magnitude from simulation and field structure from experimental images. a, 3D OSIRIS simulation of the system after 1 ns of interaction between the counter-streaming 1,900 km s^{-1} plasma flows (approximately 3 ns after the experimental drive laser pulse; flows enter from top and bottom). Magnetic fields are shown qualitatively in the blue/red colour scale, with electron density in orange. **b**, Magnetic field slice (transverse magnetic field component B_y) along the *y*-axis midplane, at the same time, illustrating the presence of strong filaments associated with the Weibel instability. **c**, Plasma magnetization, σ, as a function of time. When the flows are initiated with zero initial magnetic field (dashed lines) the magnetizations remain at zero until the flows begin interacting, between 2 and 3 ns. When initial toroidal fields are included consistent with the Biermann-battery mechanism, the perpendicular magnetization is ~0.1% before the flows interact (solid coloured lines). In both cases the magnetic energy associated with Weibel instability increases sharply after the flows interact, increasing σ by a factor greater than ten in several ns. The magnetization due to the ion Weibel instability, growing at the theoretical linear growth rate, is shown in solid black. This calculation shows that the Weibel-generated magnetization becomes the dominant contribution to the overall magnetization of the system. **d**, Measurement of the mean separation between filaments in experimental proton radiographs (red) and synthetic proton images from 3D PIC simulations (blue). The filament spacing approximately doubles over the 2 ns of observation. Note that time is experimental time, measured with respect to the beginning of the drive laser.

Anomalous Heating and Plasmoid Formation in a Driven Magnetic Reconnection Experiment

J. D. Hare,[1,*] L. Suttle,[1] S. V. Lebedev,[1,†] N. F. Loureiro,[2] A. Ciardi,[3] G. C. Burdiak,[1] J. P. Chittenden,[1] T. Clayson,[1] C. Garcia,[1] N. Niasse,[1] T. Robinson,[1] R. A. Smith,[1] N. Stuart,[1] F. Suzuki-Vidal,[1] G. F. Swadling,[1,‡] J. Ma,[4] J. Wu,[5] and Q. Yang[6]

The colliding plasma flows were supersonic ($M_s \sim 1.6$) but sub-Alfvénic ($M_A \sim 0.7$), and therefore the thermal and dynamic plasma betas (ratio of the thermal or ram pressure to the magnetic pressure) are close to unity ($\beta_{th} \sim 0.7$, $\beta_{dyn} \sim 0.9$). These parameters are significantly different from those found both in magnetically driven experiments, such as MRX, and in laser driven experiments,

FIG. 1. (a) Experimental setup with the geometry of the reconnection layer. The cutaway on the right array shows the current path. (b) Top view with density map (taken at $t = 272$ ns after current start) and Thomson scattering vectors. (c) Side view interferogram.

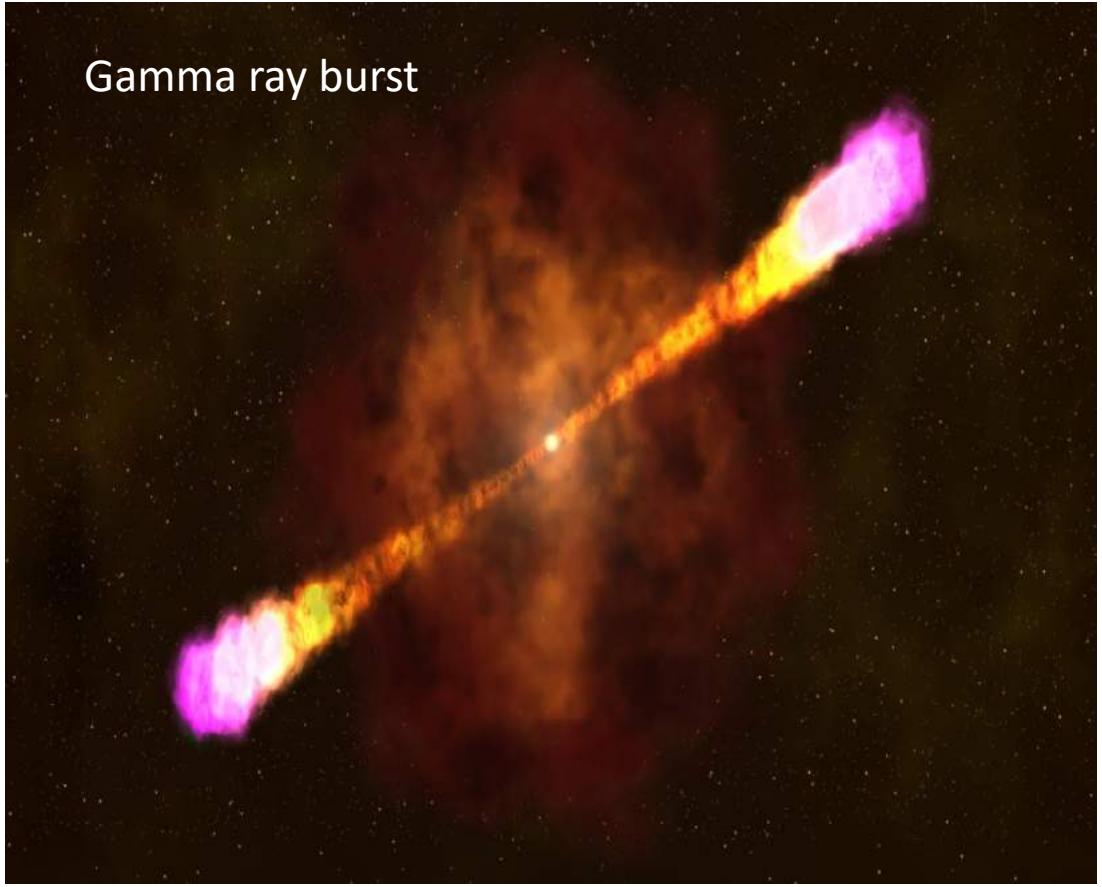
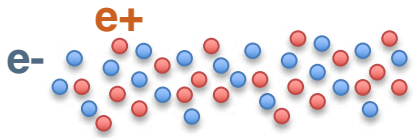
Can we create a pair plasma in the laboratory?



Positrons have the same mass as electrons, but opposite charge.



The mass symmetry removes the separation of fast and slow scales present in electron-ion plasmas.

Tsytovich & Wharton (1978) Comments Plasma Phys. Controlled Fusion (1978)

Collisionless shocks of relativistic pair plasma could be drivers of gamma emission.

Liang et al. Scientific Reports (2015) Sarri et al. Nature (2015)

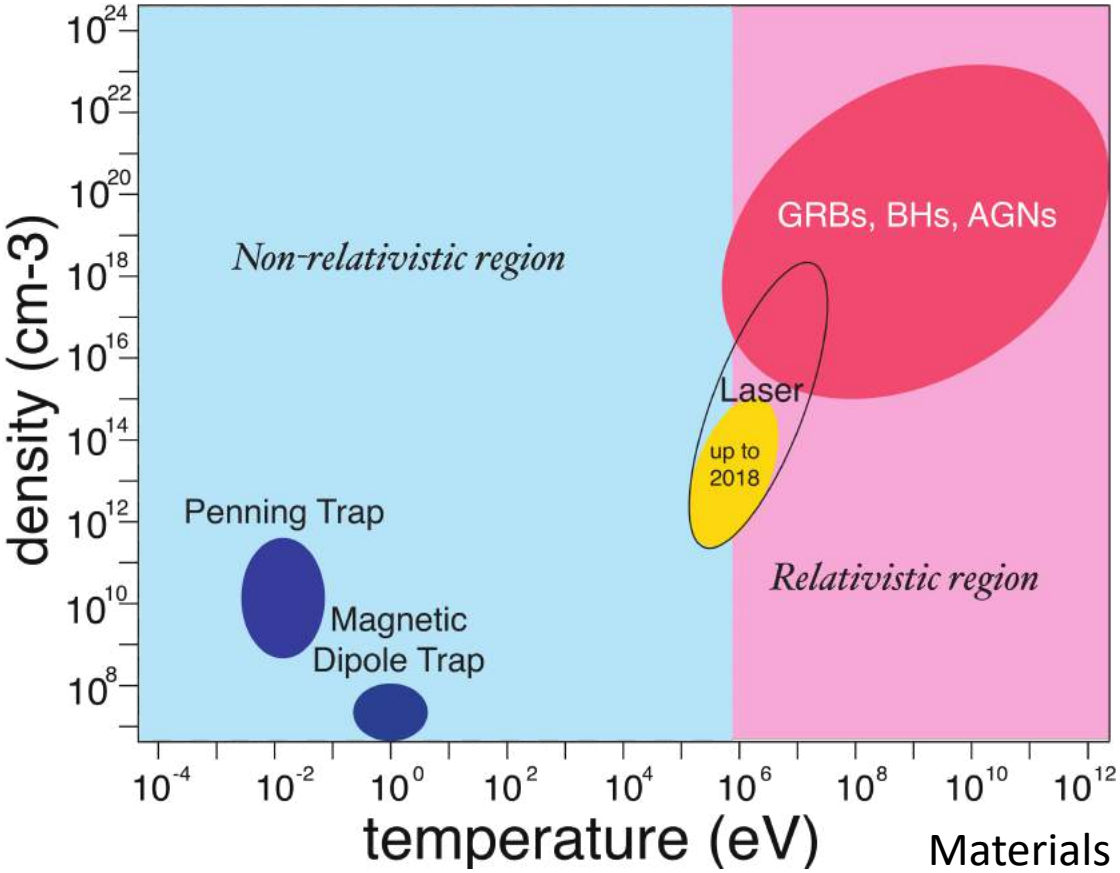
Can we create a pair plasma in the laboratory?

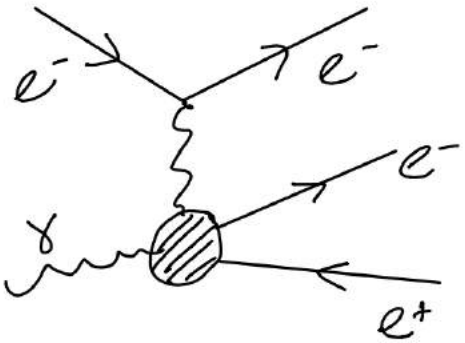


Materials from Hui Chen (LLNL)

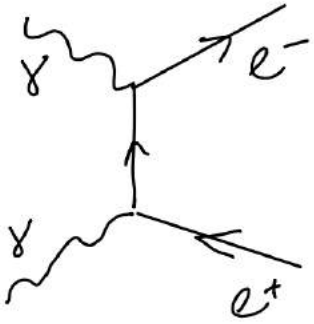
Can we create a pair plasma in the laboratory?

Positron generation processes

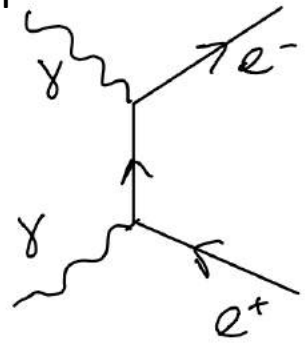
Trident process



Bethe-Heitler (BH) process



Breit-Wheeler process



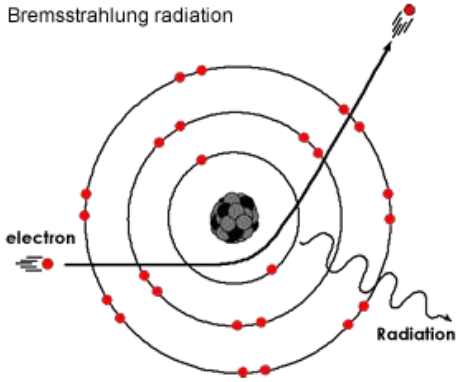
Need high energy electrons and photons

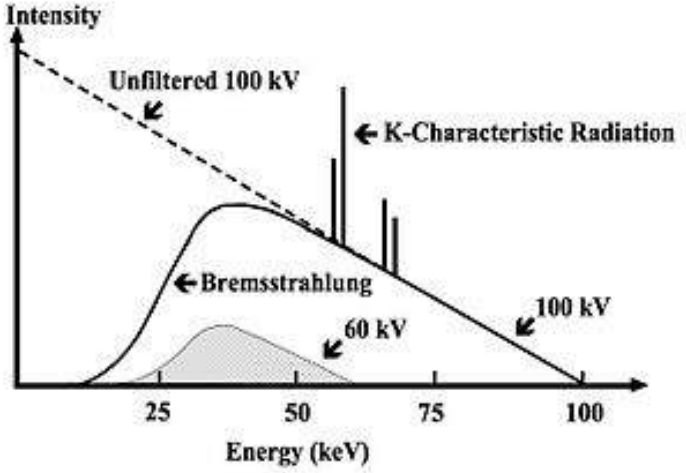
→ Generate high-energy photons through Bremsstrahlung

Can we create a pair plasma in the laboratory?

Bremsstrahlung (breaking) radiation:

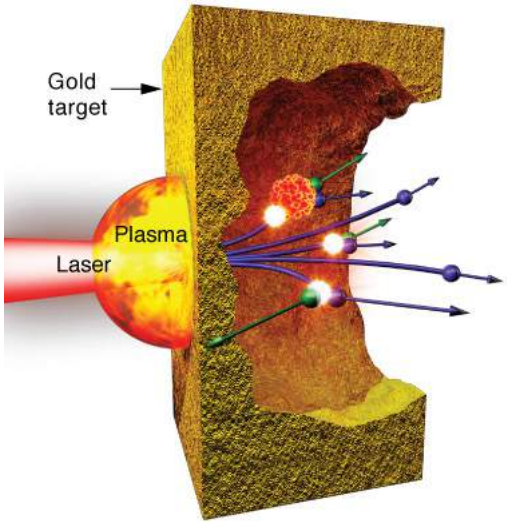
- Strong electric field of the atomic nuclei slows down and deflects an electron
- High Z nuclei have strongest effect
- Photon energies up to the highest energy electrons





Can we create a pair plasma in the laboratory?

Laser plasma interactions can generate dense, relativistic energy electron beams



H Chen, et al., PRL, 102, 105001 (2009)

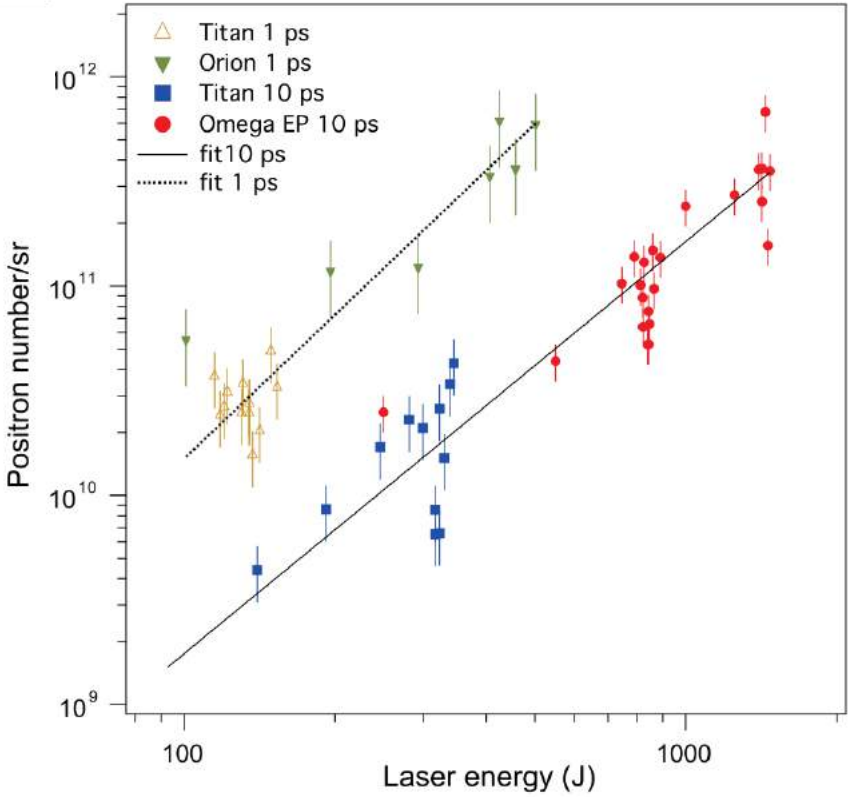
Scaling the Yield of Laser-Driven Electron-Positron Jets to Laboratory Astrophysical Applications

Hui Chen,[1] F. Fiuza,[1,2] A. Link,[1] A. Hazi,[1] M. Hill,[3] D. Hoarty,[3] S. James,[3] S. Kerr,[4] D. D. Meyerhofer,[5] J. Myatt,[5] J. Park,[1] Y. Sentoku,[6] and G. J. Williams[1]

FIG. 1 (color online). Dependence of the measured positron yield on the laser energy, E_L, obtained at three different laser facilities: Omega EP, Orion, and Titan. The upper group is from shots with 1 ps laser pulse: (brown) triangles Titan and (green) diamonds Orion. The lower group is obtained with 10 ps laser pulse: (blue) squares Titan and (red) circles Omega EP.



Can we create a pair plasma in the laboratory?

Requirements to achieve a pair plasma

- Debye length < system size

$$\lambda_D = \sqrt{\frac{\varepsilon_0 k_B T_e}{e^2 n_e}}$$

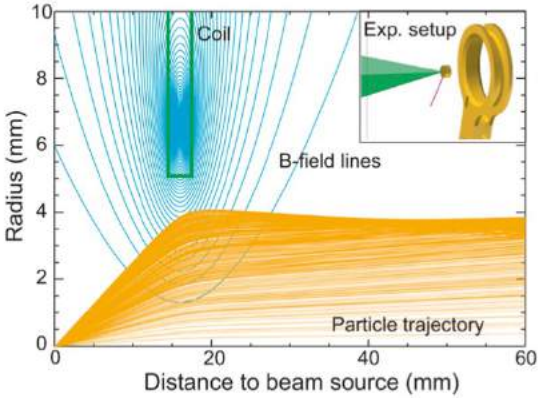
Need { large n_e — to keep system size
small $k_B T_e$ — modest

- System assembled for timescales > process of interest timescale

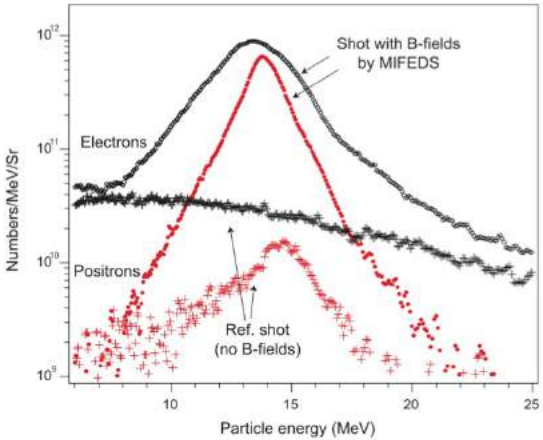
→ Need to confine the pairs → use a magnetic mirror?

Can we create a pair plasma in the laboratory?

A magnetic pulse power coil focuses the positron beam



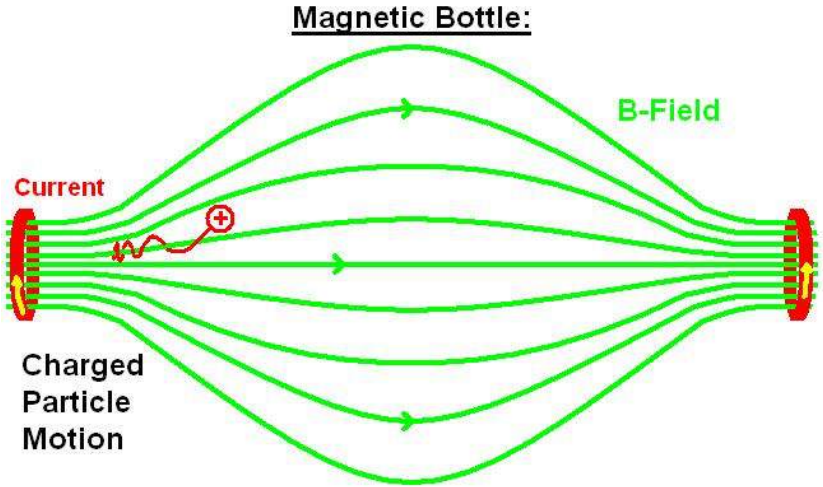
This creates an approaching quasi-neutral jet of pairs



H. Chen, et al, PoP 21, 040703, 2014

Can we create a pair plasma in the laboratory?

Magnetic mirror



Strong B-field

Weaker B-field

Strong B-field

Assume particle's magnetic moment and total energy don't change→ magnetic moment:

$$\mu = \frac{mv_\perp^2}{2B}$$

In regions of larger B, $v_\perp$ increases

But the total energy must remain constant:

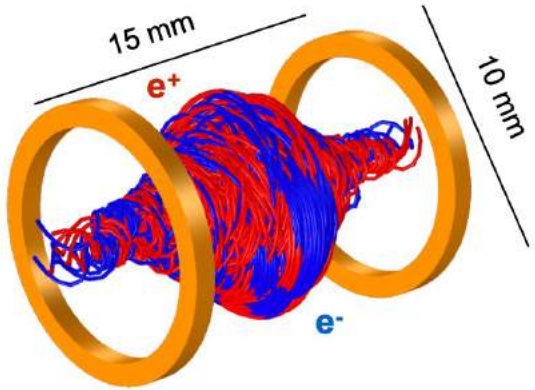
$$\varepsilon = q\phi + \tfrac{1}{2}mv_\parallel^2 + \tfrac{1}{2}mv_\perp^2$$

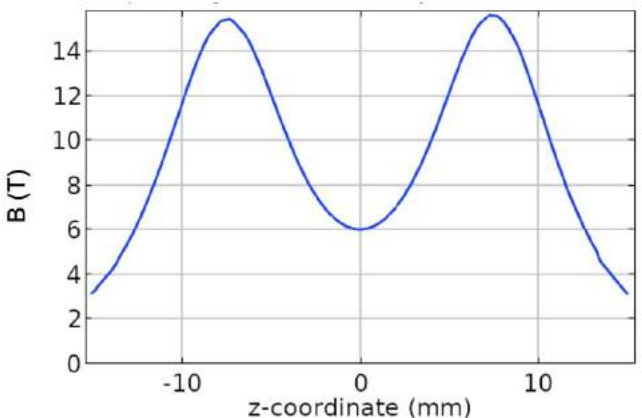
For $\phi = 0$, this means $v_\parallel$ must drop, even go negative.

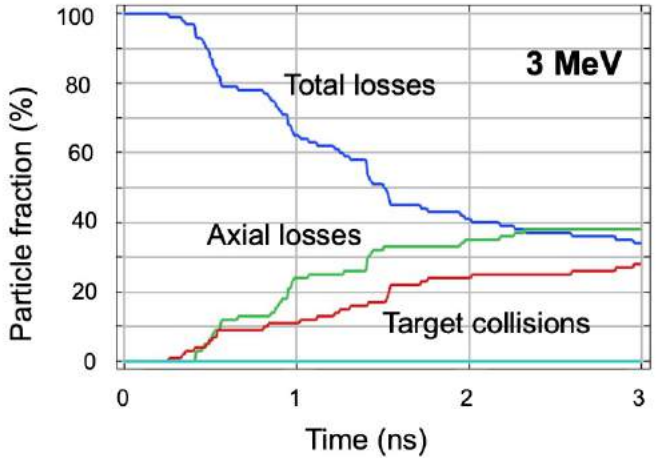
Particles bounce between coils.

Can we create a pair plasma in the laboratory?

Particle tracking indicates good mirror confinement of < 3 MeV particles

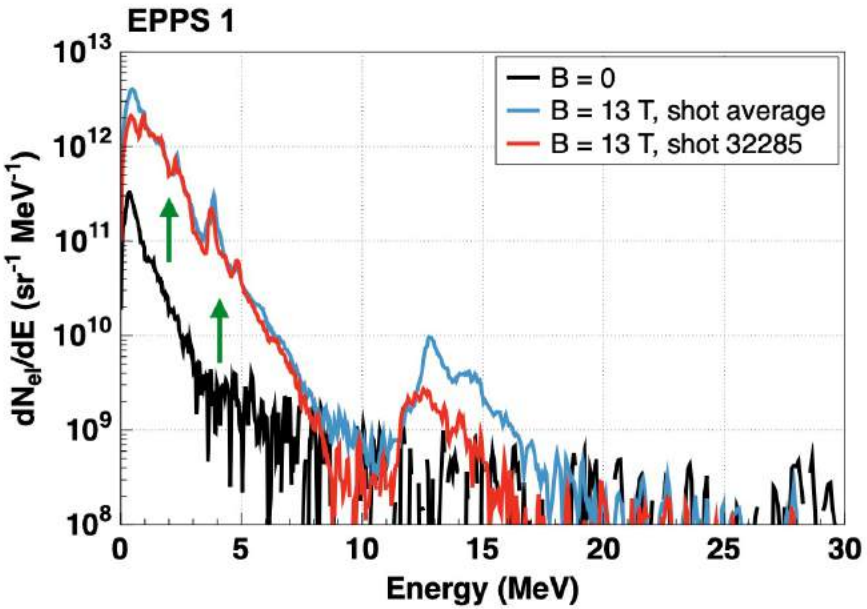


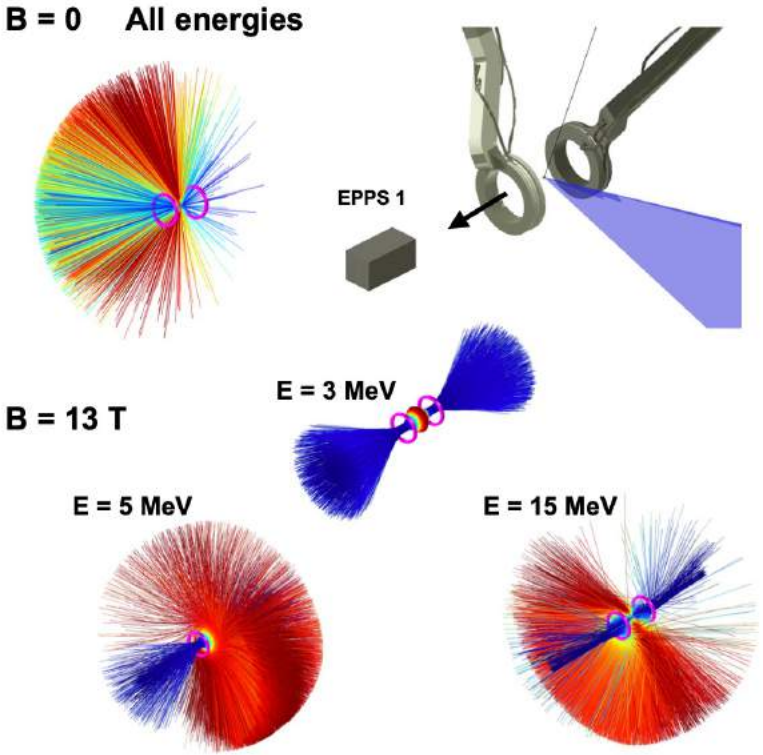




Can we create a pair plasma in the laboratory?

Axial loses increase with magnetic fields on





E < 3 MeV are well confined and only are lost axially
Axial flux of 3 MeV < E < 15 < MeV is increased
15 MeV particles are focused by B-field

Can we create a pair plasma in the laboratory?

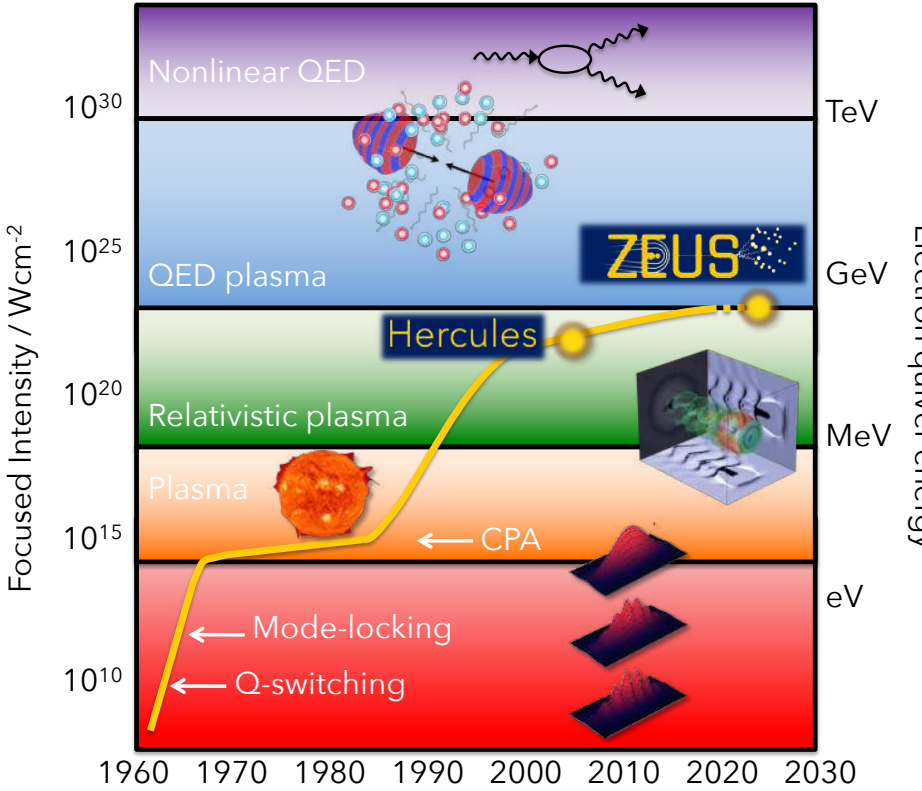
Highest positron yield = 10^{12} positrons

This 13 T magnetic mirror can contain a pairs for times of ~ nanoseconds, with $\gamma \approx 6$ and magnetization $\sigma \approx 40$. The Debye length and skin depth approach unity.

To achieve more significant pair plasma, need:

- To increase positron yield and decrease the average energy of the positrons
- And/or increase the magnetic field (to increase the particle energy that can be trapped)

Laser Intensity Frontier



$\chi = 1$
(lepton at rest)

$\chi = 1$
(lepton at energy $\sim a_0 m_e c^2$)

$a_0 = 1$

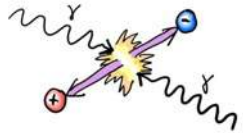
Quantum nonlinearity parameters:

$$\chi_e = \frac{||F_{\mu\nu} v^\nu||}{E_{cr}} = \frac{\text{Amplitude of } E \text{ in e rest frame}}{E_{cr}}$$

$$\chi_\gamma = \frac{||F_{\mu\nu} \hbar k^\nu||}{m_e E_{cr}} = \frac{\text{Amplitude of } E \text{ in } e^+e^- \text{ center of mass}}{E_{cr}}$$

Classical nonlinearity parameter:

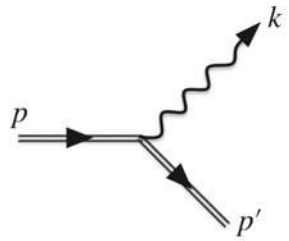
$$a = \frac{1}{2\pi} \frac{eE\lambda}{m_c c^2} = \frac{\text{Quiver energy of electron}}{m_e c^2}$$



Laser Intensity Frontier

Nonlinear Compton emission:

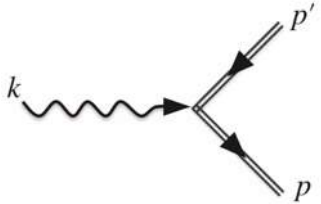
Photon emission by a (dressed) electron



Modifies charged particle dynamics

Multi-photon Breit-Wheeler

Decay of a photon to a (dressed) pair



Modifies charged particle density
